In the face of hybridization, species integrity can only be maintained through post-zygotic isolating barriers (PIBs). PIBs need not only be intrinsic (i.e. hybrid inviability and sterility caused by developmental incompatibilities), but also can be extrinsic due to the hybrid’s intermediate phenotype falling between the parental niches. For example, in migratory species, hybrid fitness might be reduced as a result of intermediate migration pathways and reaching suboptimal wintering grounds. Here, we test this idea by comparing the juvenile to adult survival probabilities as well as the wintering grounds of pied flycatchers (Ficedula hypoleuca), collared flycatchers (Ficedula albicollis) and their hybrids using stable isotope ratios of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) in feathers developed at the wintering site. Our result supports earlier observations of largely segregated wintering grounds of the two parental species. The isotope signature of hybrids clustered with that of pied flycatchers. We argue that this pattern can explain the high annual survival of hybrid flycatchers. Hence, dominant expression of the traits of one of the parental species in hybrids may substantially reduce the ecological costs of hybridization.

and first-year migrants, meaning that first-year migrants undertake their journey without parental guidance and probably alone, as in many other nocturnal migrants (Helbig 1991a; Lundberg & Alatalo 1992; Mouritsen & Larsen 1998; Berthold 2003). Pied flycatchers fly a western route, following the Iberian Peninsula and through western Africa (Cramp 1992). Mouritsen & Larsen 1998 showed experimentally that first-year pied flycatchers use the ‘clock-and-compass’ migration model, which appeared to be in accordance with ring recoveries (Mouritsen & Mouritsen 2000). The orientation mechanism in collared flycatcher has not been studied in such detail, but field observations and ring recoveries indicate that they migrate through Italy or further east, passing the Sahara desert on the eastern side (Cramp 1992). Based on ringing recoveries and visual observations, pied flycatchers winter in western to central Africa, while collared flycatchers winter in southeastern Africa (see figure 1). Observations of collared flycatchers in western Africa are generally considered to be vagrants (Cramp 1992; Lundberg & Alatalo 1992). The migratory route of hybrid flycatchers is unknown, but if they were to follow an intermediate route this would entail the crossing of large stretches of unfavourable habitat (i.e. Mediterranean Sea and central Sahara desert) as has been suggested for hybrid willow warblers (Helbig 1991a; Bensch et al. 1999).

In order to characterize the wintering locations of the pied, collared and hybrid flycatchers, we used stable isotopes extracted from feathers developed at their wintering sites in Africa, a technique that has been increasingly used over the last decade (Rubenstein & Hobson 2004 and references therein). Stable isotope ratios of the feathers reflect an individual’s diet and environmental conditions at the wintering location during feather replacement.

We tested whether hybrid individuals take an intermediate route and thereby suffer from reduced survival as well as whether they reached intermediate wintering grounds between both parental species. The latter potential scenario could result in different carbon and nitrogen isotope ratios, as these areas probably have different precipitation and vegetation types. As alternative hypotheses, we tested whether the wintering grounds of hybrids were determined by sex-linked determination or a parental-species dominance effect. The results were used to infer the most likely migratory pattern of hybrids and to evaluate the implications for post-zygotic isolation.

2. MATERIAL AND METHODS

(a) Study species and data collection
Collared and pied flycatchers are insectivorous passerine species with a breeding distribution covering most of Europe. Pied flycatchers breed in western and northern parts of Europe continuing eastwards into Russia. Collared flycatchers breed in Central and Eastern Europe. On the Baltic Islands of Gotland and Oland, both species breed sympatrically and hybridize in low numbers (approx. 3% of breeding pairs; Veen et al. 2001). Juvenile to adult survival differences were estimated from fledglings recruited back as adults to the breeding population for pied and collared flycatchers as well as hybrids, using 26 years (1980–2005) of data from breeding flycatchers on Gotland (57°10’N, 18°20’E), Sweden (for data collection methods, see Gustafsson 1989; Pärt & Gustafsson 1989). Individuals born in 2004 and 2005 may not yet have recruited and nests from those years were therefore excluded. We collected the median tertial feather of breeding flycatchers. These feathers are fully moulted on the wintering grounds before spring migration (Cramp 1992; Salewski et al. 2004) and since the flycatchers are most probably territorial (Salewski et al. 2002), we assume that the isotope ratios in these feathers reflect their diet and can be used to discern wintering location differentiation between the two species and their hybrids. The feathers were collected at the end of the breeding season, just before pre-migratory moult with permission from the CFN (number M 78-05). Blood samples from birds were collected to ensure correct species identification (see below). Blood samples (3–10 μl) were taken from the brachial vein and stored in 96% ethanol at 4°C.

(b) Species identification and molecular genetic methods
Species were identified in the field using biometrics (Svensson 1984), behavioural characteristics and vocalization. Feather samples were collected from all individuals with features that deviated from the normal species range and from pairs whose broods contained infertile eggs or low hatching success, since female hybrids (the heterogametic sex) have reduced fertility (Gelter et al. 1992). Species identity of all birds was genetically determined as part of a large-scale study on genetic introgression between the two species (G.-P. Sætre & A. Qvarnström 2006, unpublished data). These results were used to exclude backcrosses (made possible through fertile hybrid males) and eliminate identification errors. For the genetic analysis, the DNA was extracted and purified using standard phenol–chloroform extraction. Tag-array-based mini-sequencing assays were applied to genotype single nucleotide polymorphisms (SNPs) based on the methods described in Sætre et al. (2003), with the difference that in this study 45 SNPs instead of 20 SNPs were used (G.-P. Sætre & A. Qvarnström 2006, unpublished data). Individuals were
assigned as either pied, collared or F1 hybrids using the model-based cluster method described by Pritchard et al. (2000) using the same approach and setting as in Sætre et al. (2003).

The maternal species of F1 hybrids was determined using the amplification of a species-specific 32 bp indel in the mitochondrial DNA (Sætre & Moum 2000).

(c) Stable isotope analysis
The ratios of the stable isotopes $^{13}\text{C}/^{12}\text{C}$ and $^{15}\text{N}/^{14}\text{N}$ in chloroform-washed feather samples were determined at the Centre for Limnology of the Netherlands Institute of Ecology. Carbon stable isotope ratios (parts per thousand, ‰, difference from the $^{13}\text{C}/^{12}\text{C}$ ratio in Vienna PeeDoe limestone; henceforth referred to as $\delta^{13}\text{C}$) and nitrogen stable isotope ratios (‰ difference from the $^{15}\text{N}/^{14}\text{N}$ ratio in atmospheric N$_2$; henceforth referred to as $\delta^{15}\text{N}$) were determined in a HEKAtech EuroEA elemental analyser coupled online through a Finnigan con-flo interface to a Finnigan Delta S isotope ratio mass spectrometer. Average reproducibility based on replicate measurements was less than 0.2‰ for $\delta^{13}\text{C}$ and less than 0.1‰ for $\delta^{15}\text{N}$.

(d) Statistical analysis
Survival probabilities were compared between collared flycatchers, pied flycatchers and the two hybrid types (depending on their parental species pairing) using a generalized linear model (GLM) with a logit-link function and number of fledged juveniles within a nest as the denominator. The variable including the categories, collared flycatcher, pied flycatcher and both hybrid types, will henceforth be referred to as ‘species’ for ease of use. Differences in isotope values between the two species and both types of hybrid depending on their parental species paring were analysed separately for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ using a main effect ANOVA. For all the models tested, we did not find a significant deviation from normality, or an inequality of variances in the data. Besides species, sex, year and lay date (day of first egg) were also included as explanatory variables in the model. Non-significant variables were excluded from the analysis in a backwards elimination process. Pairwise differences between the species categories were analysed using a Tukey’s HSD test.

To test whether hybrids fit an intermediate isotope ratio distribution, we compared the combined weighted mean of pied and collared flycatchers to the hybrids using a one-sample $t$-test for both $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$. Statistical tests were conducted using STATISTICA v. 7.0, GenStat v. 8.0 and JMP v. 6.0.

To verify our models selected above, we conducted model selection using the Akaike Information Criteria corrected for sample size (AICc; Burnham & Anderson 2002). AIC scores for all models are presented online (electronic supplementary material, appendix 1).

3. RESULTS
The fledged juvenile to adult survival probabilities differed between the species (GLM: $\chi^2_3 = 36.76$, $p < 0.0001$). However, only the pied flycatcher had a substantially lower survival probability (mean (s.e.) = 0.038 (0.014), $n = 129$) compared with the other species (collared flycatcher: mean (s.e.) = 0.107 (0.003), $n = 3308$; father pied flycatcher, mother collared flycatcher: mean (s.e.) = 0.107 (0.023), $n = 47$; father collared flycatcher, mother pied flycatcher: mean (s.e.) = 0.096 (0.021), $n = 59$). The data were overdispersed (overdispersion parameter = 1.193) and the scaling parameter was therefore adjusted accordingly.

A total of 78 feather samples collected in 2004 and 2005 were analysed. The analyses involved 24 pied (12 males and 12 females) and 39 collared flycatchers (20 males and 19 females). Feather samples from 15 hybrids were analysed, of which 10 had a pied (3 males and 7 females) and 5 had a collared flycatcher mother (all males).

Pied and collared flycatchers, as well as their hybrids, show a clear difference in the $\delta^{13}\text{C}$ distribution (ANOVA: ‘species’: $F_{5,74}=16.93$, $p < 0.001$; all other explanatory variables: $p > 0.45$), whereas only a near significant year effect was found for $\delta^{15}\text{N}$ (ANOVA: year: $F_{1,76}=3.26$, $p=0.075$; all other explanatory variables: $p > 0.50$; figure 2a). Pied and collared flycatchers differed in $\delta^{13}\text{C}$, whereas hybrids had $\delta^{13}\text{C}$ values similar to those of pied flycatchers (Tukey’s HSD test, $p < 0.01$; figure 2b). The hybrids differed significantly from the combined weighted mean of pied and collared flycatchers for $\delta^{13}\text{C}$ ($t_{14} = -3.38$, $p = 0.003$), but not for $\delta^{15}\text{N}$ ($t_{14} = -0.97$, $p > 0.30$).

Figure 2. $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ isotope ratios for (a) pure pied (PF) and collared (CF) flycatchers and (b) hybrid individuals with maternal species in brackets.
The isotope ratio results above are supported by analyses using model selection theory (see electronic supplementary material, appendix 1).

4. DISCUSSION

Differences in stable isotope ratios in the feathers of collared and pied flycatchers, moulted at the wintering site, were consistent with the presumed largely segregated wintering grounds of the two species. The feather isotope data of the hybrids suggest that the hybrids, regardless of parental species pairing, fall within the range of pied flycatchers.

That the average isotope ratios for nitrogen are indistinguishable for pied and collared flycatchers is in accordance with the recent findings in willow warbler feathers collected in West and Central–East Africa (Bensch et al. 2006). Bensch et al. also found West African willow warbler feathers to have lower carbon isotope ratios than those from Central–East Africa. This exactly mirrors the isotopic findings in pied and collared flycatchers, which are supposedly wintering in West and Central–East Africa, respectively. Variation in carbon is often attributed to the relative abundance of plants using C3 or C4 photosynthetic pathways (Smith & Epstein 1971; Rubenstein & Hobson 2004 and references herein). When using global C3/C4 plant distributions (Still et al. 2003), the pattern found for the willow warblers and flycatchers is opposite to the predicted pattern. However, qualitatively identical patterns found by Bensch et al. 2006 not only validate our findings, but also show that there is need for a better mechanistic understanding of isotope distribution (e.g. Kelly 2000).

Since variation in isotope ratios in tissues is both influenced by environmental and dietary differences, it is important to assess which of these factors is determining the observed stable isotope patterns among the flycatchers in this study. In other words, could the flycatchers winter at the same geographical location but differ in diet, or are they wintering at different locations? There are various studies indicating that dietary choice of pied and collared flycatchers are very similar. Prey items taken by the two flycatcher species during the breeding period largely overlap (Bures 1995). Moreover, nestlings of both species can be successfully raised by foster parents of the alternative species (Qvarnström et al. 2005). On the wintering grounds, the pied flycatcher is an opportunist forager with a broad diet, which is a common feature of migratory species compared to residents (Salewski et al. 2002). These observations suggest that the differences in feather isotope signatures reflect geographical differences in wintering sites and are not an effect of differences in diet within a single geographical range. This, together with the previously described differences in wintering range between pied and collared flycatchers (Cramp 1992; Lundberg & Alatalo 1992), which matches the isotopic findings in willow warbler feathers collected in these same ranges (Bensch et al. 2006) makes us confident in our conclusion that the two species have segregated wintering distributions. We acknowledge that one of the drawbacks of the now widely used isotope approach is that if no differences in isotope values are found, it does not necessarily mean that the geographical areas are the same. In the future, research such as that conducted by Bensch and his colleagues (2006), resulting in detailed isotope-based maps, will make the linkage between isotope values and geographical area more accurate.

With respect to the hybrid’s determination of the wintering grounds, three obvious hypotheses could be put forward. Firstly, determination of the wintering grounds could be additive, which results in ‘intermediate’ wintering grounds of hybrids. This hypothesis can most likely be excluded, as the survival probabilities of the two hybrid types were as high as that of collared flycatchers and higher compared with pied flycatchers. Further, δ13C of hybrids significantly differed from the predicted intermediate isotope ratio of both parental species. However, the latter test assumes a clear-cut difference in habitat types at the contact zone of the parental species. Such assumptions can be tested and further insights gained, once a more accurate linkage between isotope ratios and geographical location becomes available.

Secondly, the determination of wintering grounds could be sex linked, in which case hybrids should have isotope ratios overlapping those of both parental species. In the case of Z-linkage, the wintering range would be paternally determined in daughters (ZW). Alternatively, wintering grounds could be maternally determined through the W chromosome (resulting in maternal inheritance in daughters) or cytoplasmic DNA inheritance (resulting in complete maternal inheritance). Neither of these hypotheses is supported by our data, but the sample sizes are small making firm conclusion difficult.

Thirdly, dominance of the determination of wintering grounds of one species would create the clustering of hybrids with one parental species, which is consistent with the observed pattern. The most parsimonious explanation for our data is that the pied flycatcher’s migration route is dominant and hence all hybrids follow this route. This would explain both the lack of a reduced survival among hybrids, since these hybrids do not follow an intermediate and potentially suboptimal migration route (Helbig 1991b; Bensch et al. 1999) and the clustering of hybrids with pied flycatchers based on isotope ratios.

Sutherland (1998) states that ‘the change (of migration routes) will be most rapid when the genetic system is simple, there is assortative mating or the new route is dominant...’. In this study, we find indications for dominance in migratory traits when two populations hybridize, but an important question is whether dominance can evolve within populations and whether it has done so. Recently, there has been much discussion on the evolutionary potential of migratory traits (Berthold 2003; Pulido & Berthold 2003; Pulido & Widmer 2005) and an increasing body of evidence suggests that maintaining genetic variation and hence the potential for a response to selection of these traits is adaptive (e.g. Berthold et al. 1992; Sutherland 1998; Bearhop et al. 2005). Dominance effects in migratory traits therefore need to be taken into consideration, since they can have marked effects on the evolution of changes in migratory traits.

More recently, an interest in the potential effects of changes in migratory behaviour on reproductive isolation has arisen. Bearhop et al. (2005) argue that in blackcaps, a switch of wintering location can lead to temporal segregation of sympatric breeding populations and eventually lead to reproductive isolation and sympatric speciation. At the moment, the effect of an accelerated
change of migration route on speciation is still poorly understood and remains a challenge to be solved.

To our knowledge, this is the first study to find indications of a dominance effect on the location of wintering grounds between two closely related species. By following one of the parental species’ migration routes and using their wintering grounds, hybrids will not bear the potential costs of an intermediate migration route. Thereby, the dominance effect reduces the extrinsic post-zygotic isolation between the two flycatcher species, since hybrid individuals do not suffer from intermediate maladaptive traits. Further, species integrity is negatively affected by the reduced reproductive isolation between the two species. Not only can the observed dominance effect in migratory traits affect reproductive isolation, but also it can have implication for the speed with which migratory traits can change in response to a changing environment.

We would like to thank Harry Korthals for the stable isotope ratio determinations; Ben Sheldon, Franjo Weissing, Francisco Pulido, Thomas Alerstam, Lars Gustafsson and two anonymous referees for helpful comments and discussions during preparation of the manuscript; Reija Duva, Glenn-Peter Sætre and Chris Wiley for help in the laboratory and Dick Visser for making figure 1.
